

Computer Science 160

Translation of Programming Languages

Instructor: Christopher Kruegel
(based on material by Tim Sherwood)

Code Generation

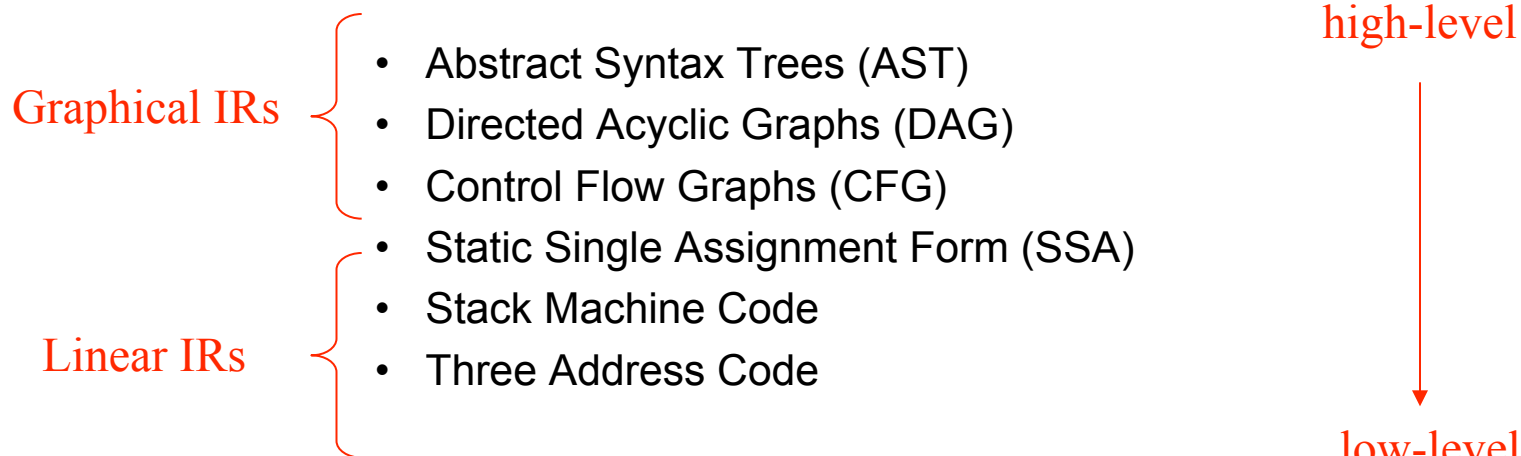

Overview

UC Santa Barbara

- Intermediate Representations
 - There is more than one way to represent code as it is being generated, analyzed, and optimized (we use ASTs)
 - How code runs
 - The way code runs on a machine depends on if the code is compiled or interpreted, and if it is statically or dynamically linked
 - Code Generation
 - Three-address code and stack code
 - Dealing with Boolean values and control (such as loops)
 - Arrays
-

Intermediate Representations

UC Santa Barbara

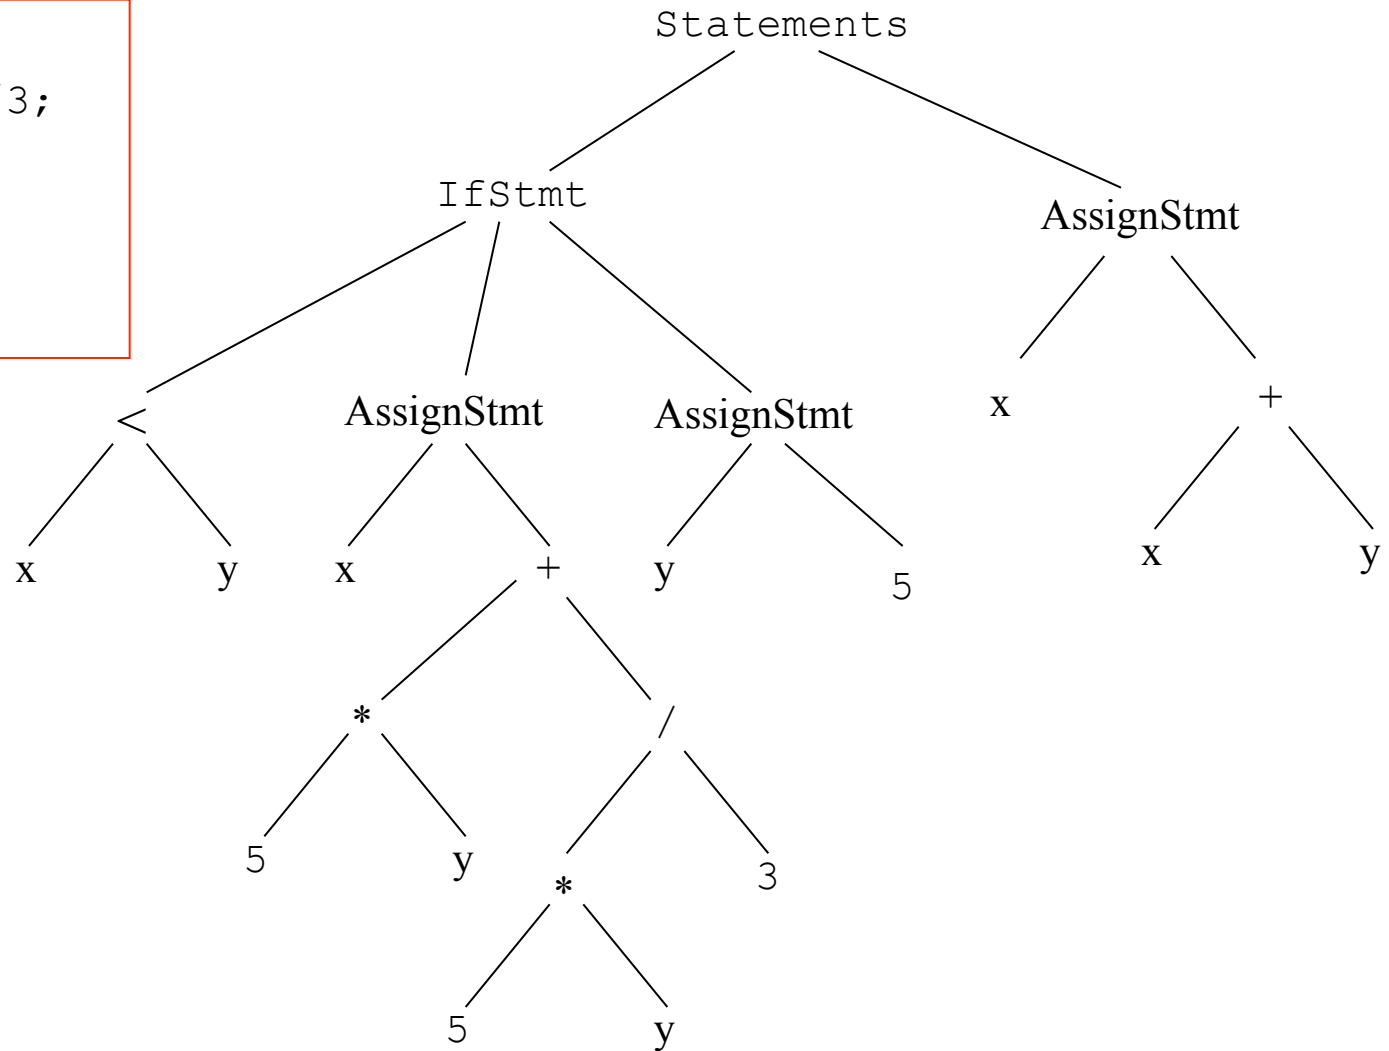

- Hybrid approaches mix graphical and linear representations
 - MIPS compilers use ASTs for loops if-statements and array references
 - Use three-address code in basic blocks in control flow graphs

Abstract Syntax Trees (ASTs)

UC Santa Barbara

```
if (x < y)
  x = 5*y + 5*y/3;
else
  y = 5;
x = x+y;
```

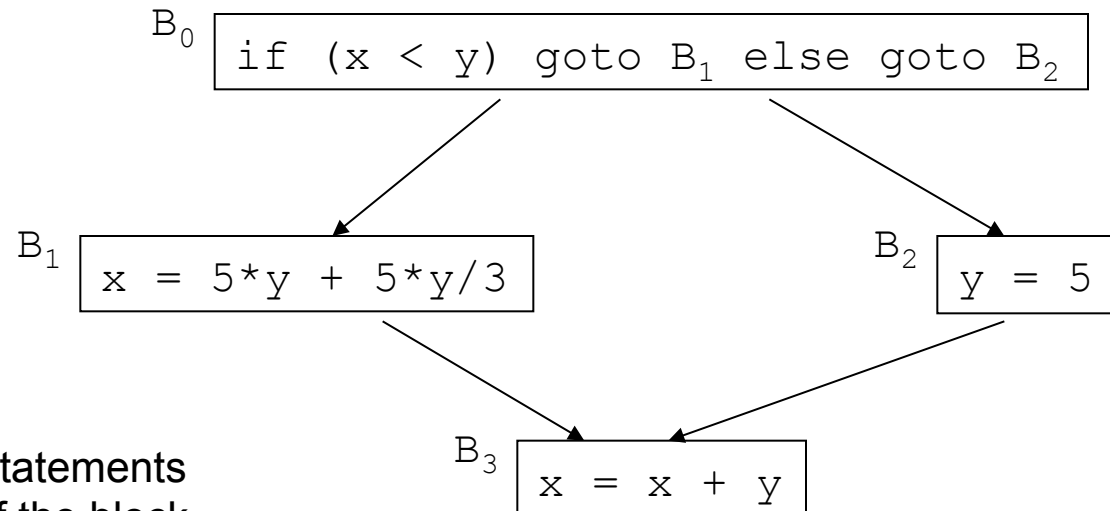

Control Flow Graphs (CFGs)

UC Santa Barbara

- Nodes in the control flow graph are basic blocks
 - A *basic block* is a sequence of statements always entered at the beginning of the block and exited at the end
- Edges in the control flow graph represent the control flow

```
if (x < y)
  x = 5*y + 5*y/3;
else
  y = 5;
x = x + y;
```

- Each block has a sequence of statements
- No jump from or to the middle of the block
- Once a block starts executing, it will execute till the end

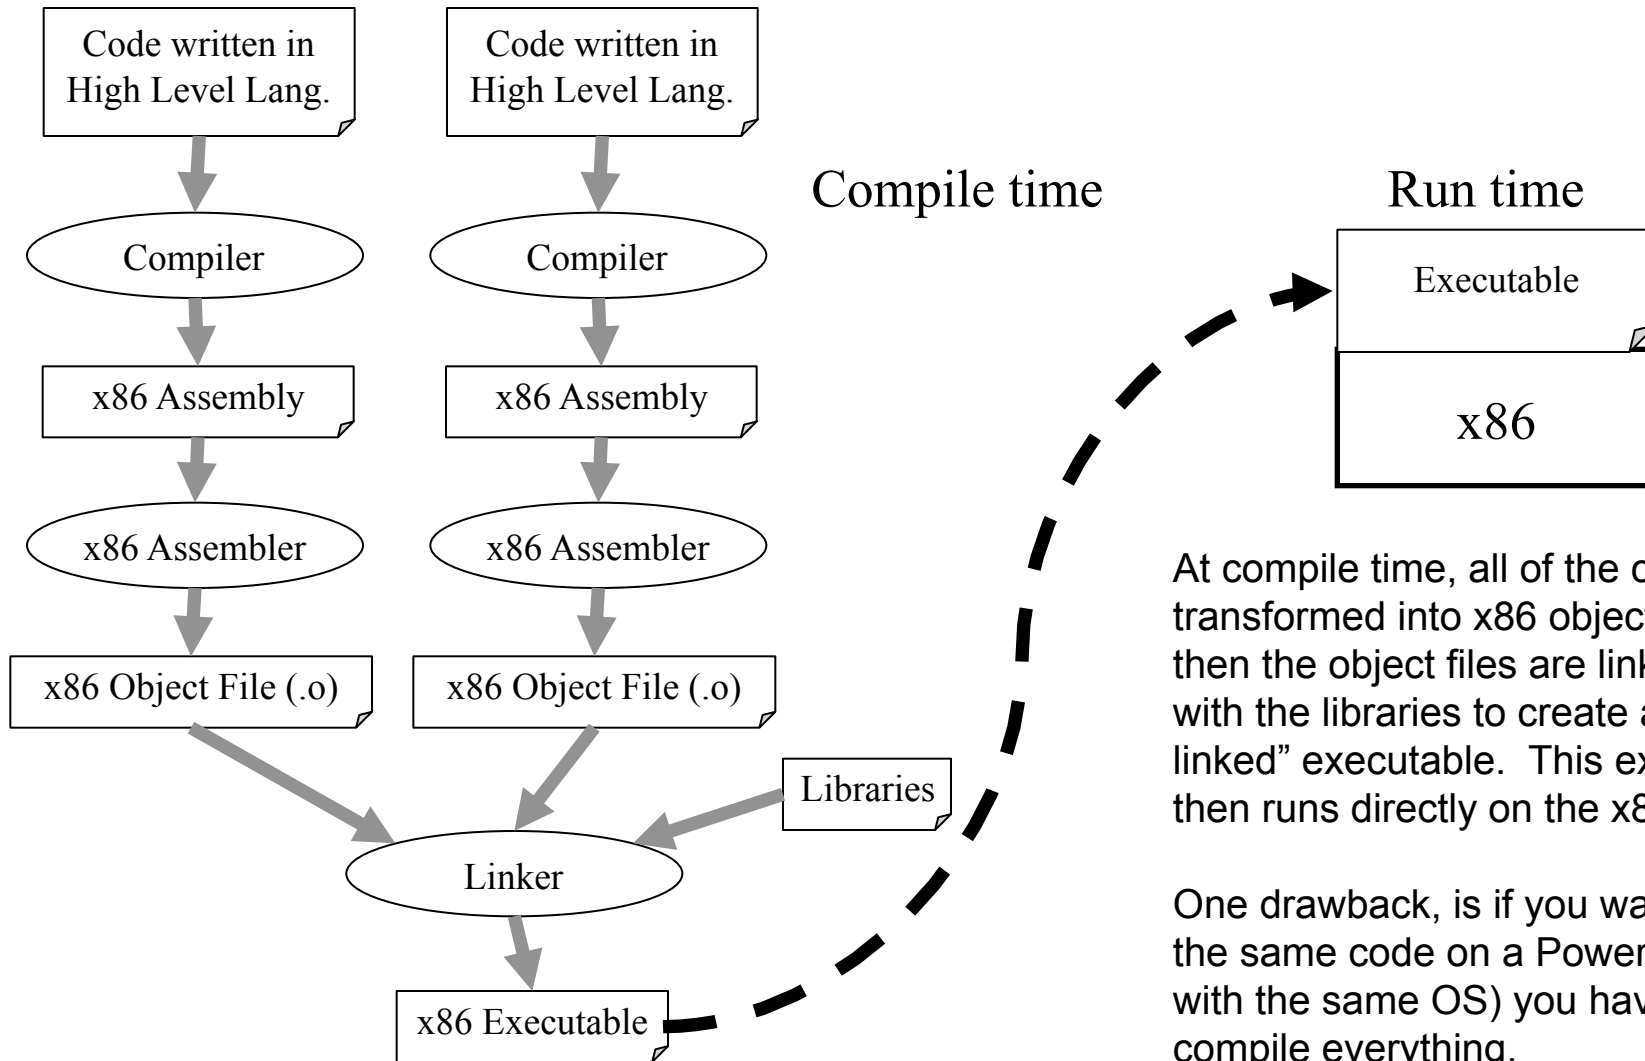

Code Generation

UC Santa Barbara

- To generate actual code that can run on a processor (such as gcc) or on a virtual machine (such as javac) we need to understand what code for each of these machines looks like.
 - Rather than worry about the exact syntax of a given assembly language, we instead use a type of pseudo-assembly that is close to the underlying machine.
 - In this class, we need to worry about 2 different types of code
 - Stack based code: Similar to the Java Virtual Machine
 - Three-address code: Similar to most processors (x86, Sparc, ARM, ...)
-

x86 C Compiler with Static Linking

UC Santa Barbara

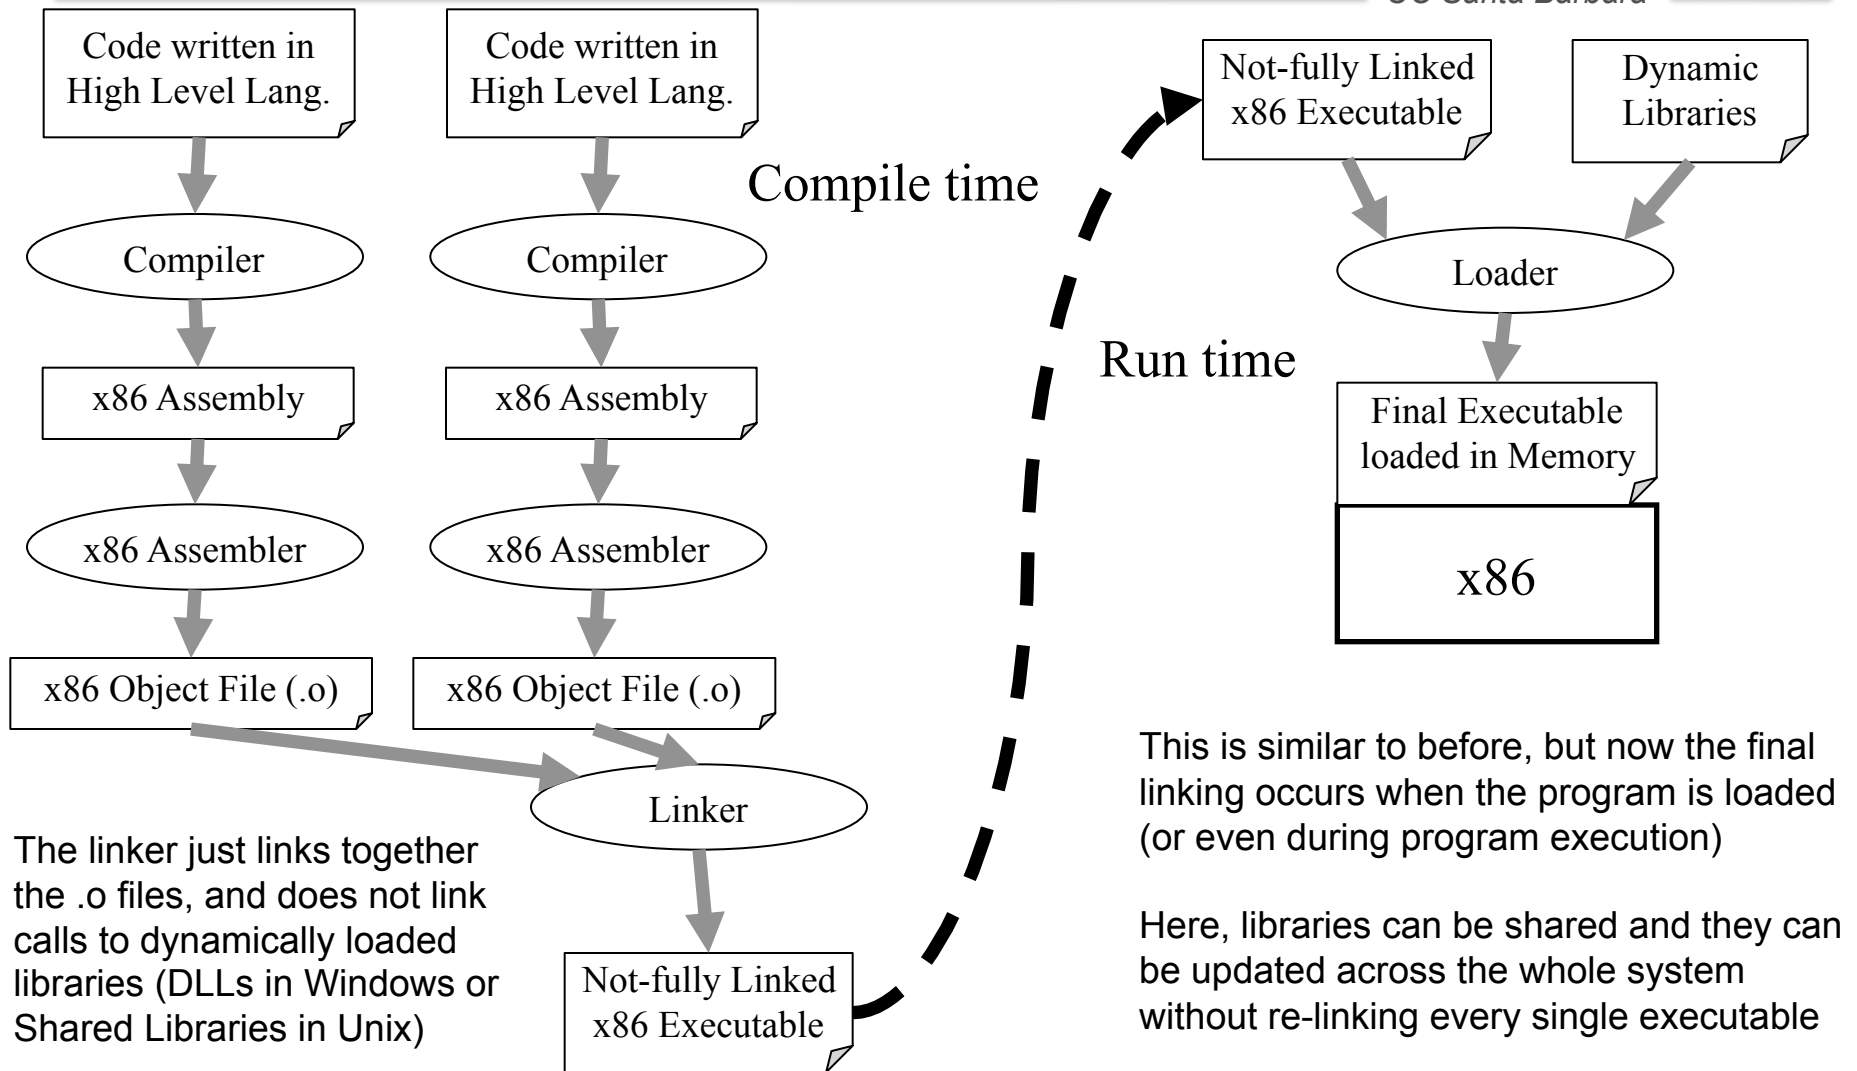

At compile time, all of the code is transformed into x86 object files and then the object files are linked together with the libraries to create a “statically linked” executable. This executable then runs directly on the x86 hardware.

One drawback, is if you wanted to run the same code on a Power-PC (even with the same OS) you have to re-compile everything.

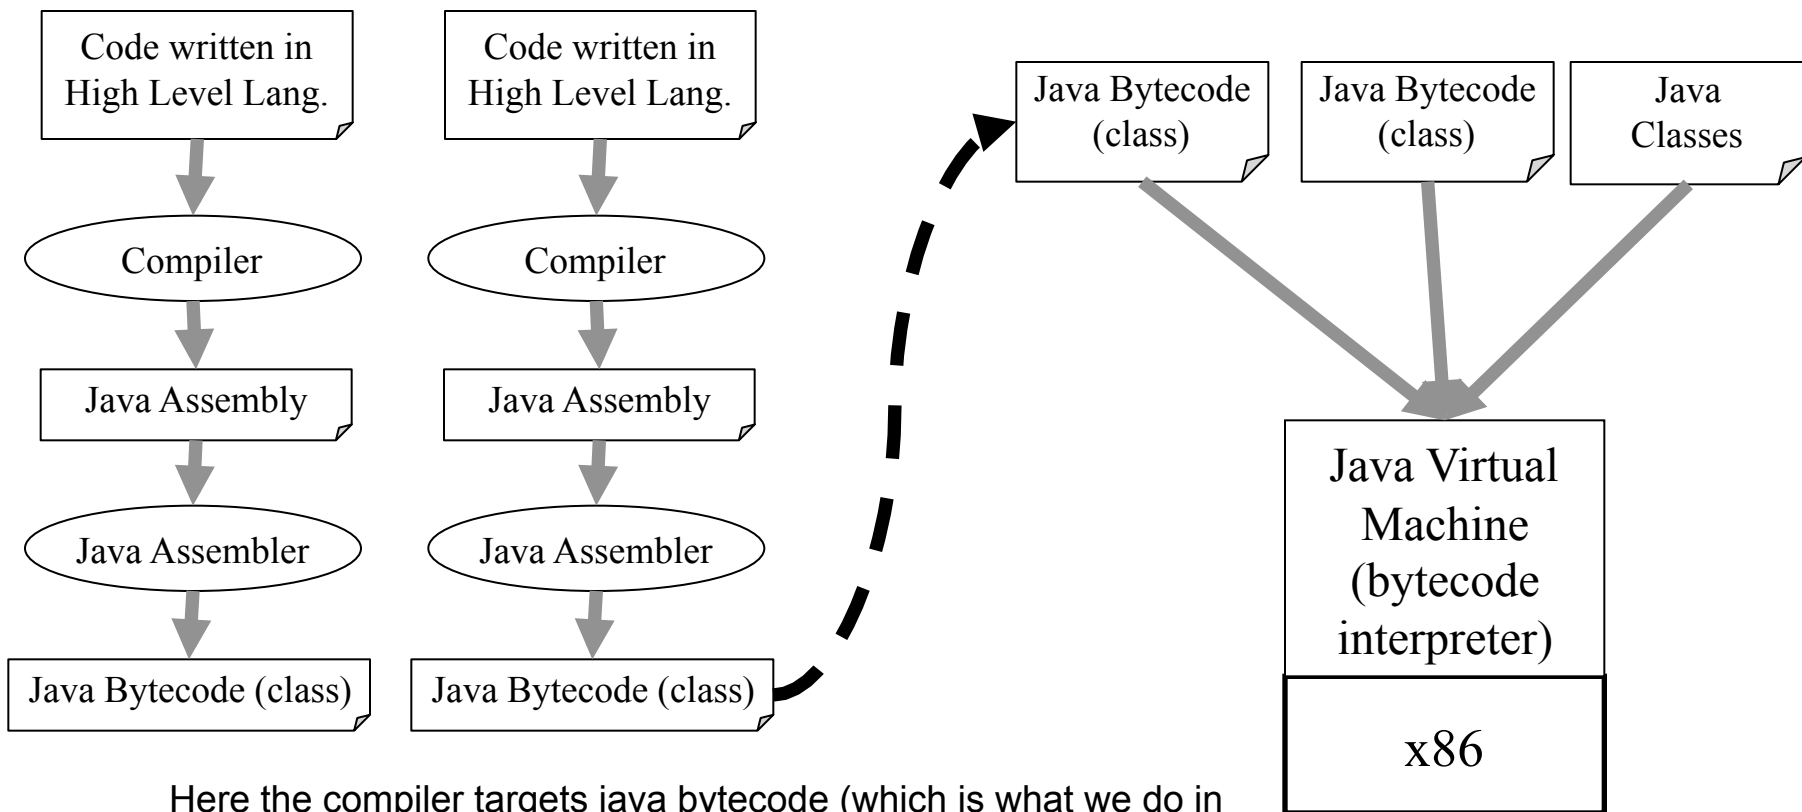

x86 C Compiler with Dynamic Linking

UC Santa Barbara

Java Compiler

UC Santa Barbara

Here the compiler targets java bytecode (which is what we do in this class) and the bytecode is then run on top of the Java Virtual Machine (JVM). The JVM really just interprets (simulates) the bytecode like any scripting language. Because of this, any java program compiled to bytecode is portable to any machine that someone has already ported the JVM too. No need to recompile.

Three-Address Code

UC Santa Barbara

- Each instruction can have at most three operands
- We have to break large statements into little operations that use temporary variables
 - $X=(2+3)+4$ turns into $T1=2+3; X=T1+4;$
- Temporary variables store the results at the internal nodes in the AST
- Assignments
 - $x := y$
 - $x := y \text{ op } z$ *op: binary arithmetic or logical operators*
 - $x := \text{op } y$ *op: unary operators (minus, negation, integer to float)*
- Branch
 - $\text{goto } L$ *execute the statement with labeled L next*
- Conditional Branch
 - $\text{if } x \text{ relop } y \text{ goto } L$ *relop: <, =, <=, >=, ==, !=*
 - if the condition holds, we execute statement labeled L next
 - if the condition does not hold, we execute the statement following this statement next

Three-Address Code

UC Santa Barbara

```
if (x < y)
  x = 5*y + 5*y/3;
else
  y = 5;
x = x + y;
```

Variables can be represented with their locations in the symbol table

```
if x < y goto L1
goto L2
L1: t1 := 5 * y
    t2 := 5 * y
    t3 := t2 / 3
    x := t1 + t2
    goto L3
L2: y := 5
L3: x := x + y
```

Temporaries: temporaries correspond to the internal nodes of the syntax tree

- Three-address code instructions can be represented as an array of
quadruples: operation, argument1, argument2, result
triples: operation, argument1, argument2
(each triple implicitly corresponds to a temporary)

Stack Machine Code

UC Santa Barbara

- Stack based code uses the stack to store temporary variables
 - When we evaluate an expression $(E+E)$, it will take its arguments off the stack, add them together and put the result back on the stack.
 - $(2+3)+4$ will push 2; push 3; add; push 4; add
 - The machine code for this is a bit more ugly but the code is actually easier to generate because we do not need to handle temporary variables.
-

Stack Machine Code

UC Santa Barbara

```
if (x < y)
  x = 5*y + 5*y/3;
else
  y = 5;
x = x+y;
```

pushes the value
at the location x to
the stack

```
load x
load y
iflt L1
goto L2
L1: push 5
load y
multiply
push 5
load y
multiply
push 3
divide
add
store x
goto L3
L2: push 5
store y
L3: load x
load y
add
store x
```

pops the top
two elements and
compares them

pops the top two
elements, multiplies
them, and pushes the
result back to the stack

stores the value at the
top of the stack to the
location x

JVM: A stack machine

- JVM interpreter executes the bytecode on different machines
- JVM has an operand stack which we use to evaluate expressions
- JVM provides 65,535 local variables for each method. The local variables are like registers so we do not have to worry about register allocation
- Each local variable in JVM is denoted by a number between 0 and 65535 (x and y in the example will be assigned unique numbers)

Code

UC Santa Barbara

- Three-Address Code:
 - Good - Compact representation
 - Good - Statement is “self contained” in that it has the inputs, outputs, and operation all in one “instruction”
 - Bad - Requires lots of temporary variables
 - Bad - Temporary variables have to be handled explicitly
 - Stack Based Code:
 - Good – No temporaries, everything is kept on the stack
 - Good – It is easy to generate code for this
 - Bad – Requires more instructions to do the same thing
-

Stack Based Code Generation

UC Santa Barbara

Attributes:	$E.code$: sequence of instructions that are generated for E <i>(no place for an expression is needed since the result of an expression is stored in the operand stack)</i>
Procedures:	newtemp(): Returns a new temporary each time it is called gen(): Generates instruction (have to call it with appropriate arguments) lookup(id.name): Returns the location of id from the symbol table

Productions

$S \rightarrow id := E$

$E \rightarrow E_1 + E_2$

$E \rightarrow E_1 * E_2$

$E \rightarrow (E_1)$

$E \rightarrow - E_1$

$E \rightarrow id$

Semantic Rules

$id.place \leftarrow \text{lookup}(id.name);$

$S.code \leftarrow E.code \parallel \text{gen}(\text{'store' } id.place);$

$E.code \leftarrow E_1.code \parallel E_2.code \parallel \text{gen}(\text{'add'});$

(arguments for the add instruction are in the top of the stack)

$E.code \leftarrow E_1.code \parallel E_2.code \parallel \text{gen}(\text{'multiply'});$

$E.code \leftarrow E_1.code;$

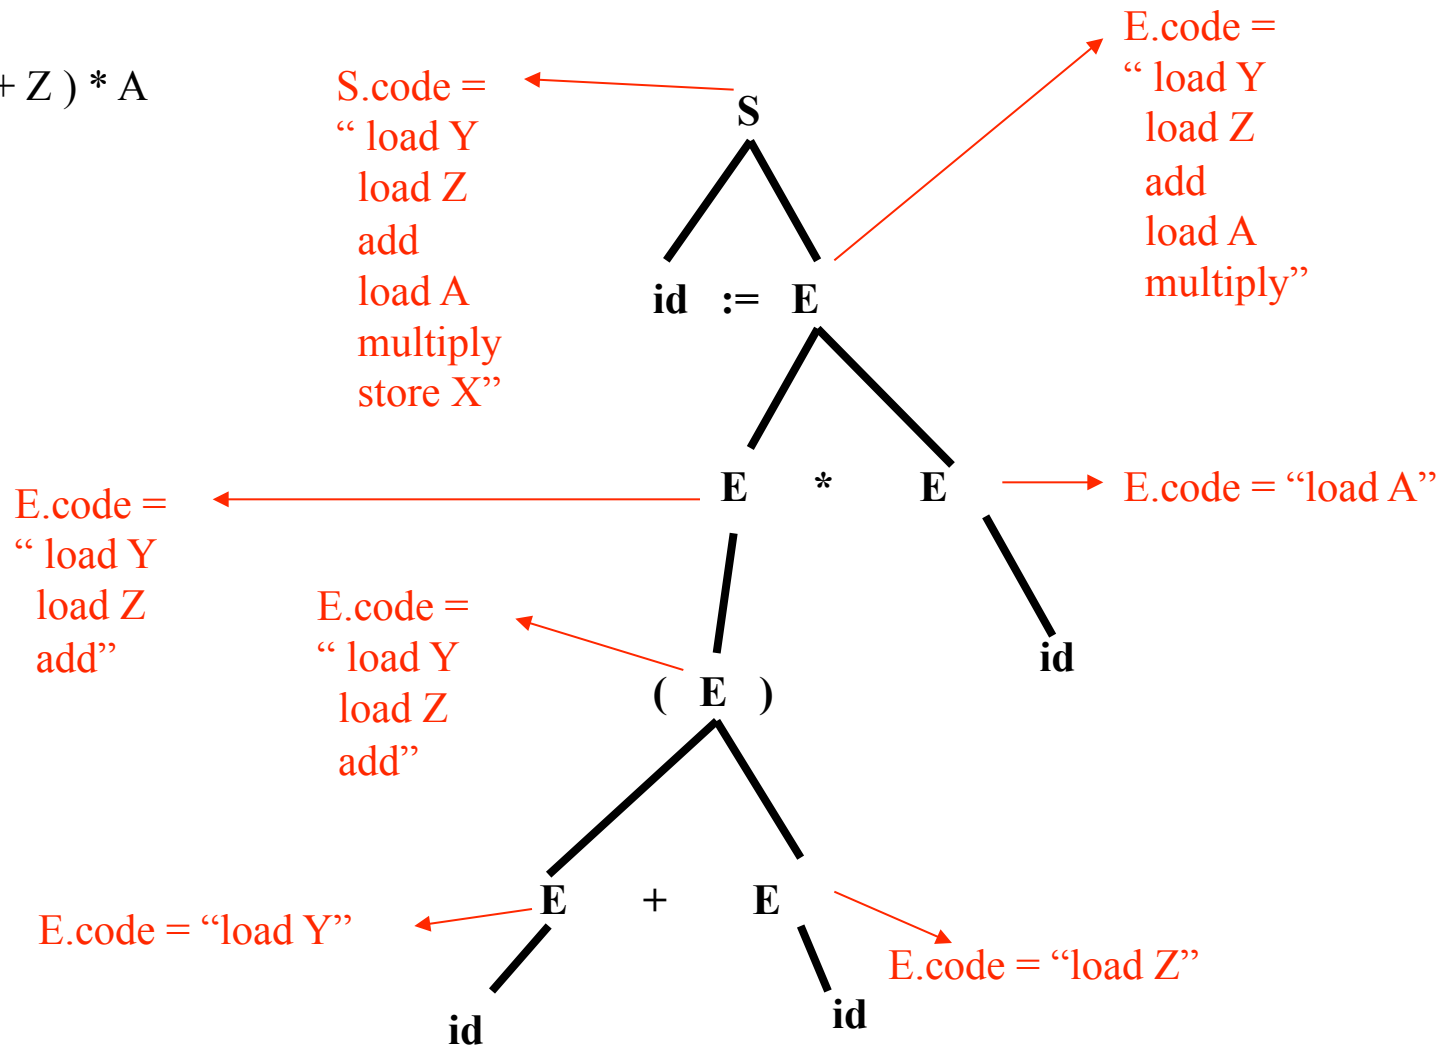

$E.code \leftarrow E_1.code \parallel \text{gen}(\text{'negate'});$

$E.code \leftarrow \text{gen}(\text{'load' } id.place)$

Example

UC Santa Barbara

$X := (Y + Z) * A$

Three-Address Code

UC Santa Barbara

Attributes:	$E.place$: location that holds the value of expression E $E.code$: sequence of instructions that are generated for E
Procedures:	<code>newtemp()</code> : Returns a new temporary each time it is called <code>gen()</code> : Generates instruction (have to call it with appropriate arguments) <code>lookup(id.name)</code> : Returns the location of id from the symbol table

Productions

$S \rightarrow id := E$

$E \rightarrow E_1 + E_2$

$E \rightarrow E_1 * E_2$

$E \rightarrow (E_1)$

$E \rightarrow - E_1$

$E \rightarrow id$

Semantic Rules

$id.place \leftarrow lookup(id.name);$

$S.code \leftarrow E.code \parallel gen(id.place := E.place);$

$E.place \leftarrow newtemp();$

$E.code \leftarrow E_1.code \parallel E_2.code \parallel gen(E.place := E_1.place + E_2.place);$

$E.place \leftarrow newtemp();$

$E.code \leftarrow E_1.code \parallel E_2.code \parallel gen(E.place := E_1.place * E_2.place);$

$E.code \leftarrow E_1.code;$

$E.place \leftarrow E_1.place;$

$E.place \leftarrow newtemp();$

$E.code \leftarrow E_1.code \parallel gen(E.place := 'uminus' E_1.place);$

$E.place \leftarrow lookup(id.name);$

$E.code \leftarrow ''$ (empty string)

Example

UC Santa Barbara

$X := (Y + Z) * A$

Code Generation for Boolean Expressions

UC Santa Barbara

- Two approaches
 - Numerical representation
 - Implicit representation
 - Numerical representation
 - Use 1 to represent true, use 0 to represent false
 - For three-address code, store this result in a temporary
 - For stack machine code, store this result on the stack
 - Implicit representation
 - For the Boolean expressions that are used in flow-of-control statements (such as if-statements, while-statements etc.) Boolean expressions do not have to explicitly compute a value, they just need to branch to the right instruction
 - Generate code for Boolean expressions that branch to the appropriate instruction based on the result of the Boolean expression
-

Boolean Expressions: Numerical Representation

UC Santa Barbara

Attributes :	<i>E.place</i> : location that holds the value of expression <i>E</i> <i>E.code</i> : sequence of instructions that are generated for <i>E</i> <i>id.place</i> : location for <i>id</i> <i>relop.func</i> : the type of relational function
--------------	--

If there are instructions in the architecture that support operations on Boolean data (like “logical and” or “logical or”), then the easiest way to implement Boolean data is to just treat it like normal data

Productions

$E \rightarrow id_1 \text{ relop } id_2$

$E \rightarrow E_1 \text{ and } E_2$

Semantic Rules

$E.place \leftarrow \text{newtemp}();$
 $E.code \leftarrow id_1.code$
 $\parallel id_2.code$
 $\parallel \text{gen}(E.place \text{ ‘:=’ } id_1.place \text{ relop.func } id_2.place)$

$E.place \leftarrow \text{newtemp}();$
 $E.code \leftarrow E_1.code$
 $\parallel E_2.code$
 $\parallel \text{gen}(E.place \text{ ‘:=’ } E_1.place \text{ ‘and’ } E_2.place);$

Boolean Expressions: Implicit Representation

UC Santa Barbara

Attributes :
E.code: sequence of instructions that are generated for *E*
E.false: instruction to branch to if *E* evaluates to false
E.true: instruction to branch to if *E* evaluates to true
(*E.code* is synthesized whereas *E.true* and *E.false* are inherited)
id.place: location for *id*

Productions

$E \rightarrow id_1 \text{ relop } id_2$

$E_0 \rightarrow E_1 \text{ and } E_2$

Semantic Rules

$E.code \leftarrow \text{gen}(\text{'if' } id_1.place \text{ relop.op } id_2.place \text{ 'goto' } E.true) \\ \parallel \text{gen}(\text{'goto' } E.false);$

$E_1.false \leftarrow E_0.false; \text{ (short-circuiting)}$

$E_2.false \leftarrow E_0.false;$

$E_1.true \leftarrow \text{newlabel}();$

$E_2.true \leftarrow E_0.true;$

$E.code \leftarrow E_1.code \parallel \text{gen}(E_1.true \text{ ':'}) \parallel E_2.code ;$

can be any relational operator:
==, <=, >= !=

These places will be filled with labels later on when they become available

This generated label will be inserted to the place for $E_1.true$ in the code generated for E_1

Example

UC Santa Barbara

These are the locations of three-address code instructions, they are not labels

Numerical representation:

```
100    if x < y goto 103
101    t1 := 0
102    goto 104
103    t1 := 1
104    if a = b goto 107
105    t2 := 0
106    goto 108
107    t2 := 1
108    t3 := t1 and t2
```

Input Boolean expression:
 $x < y$ and $a == b$

Implicit representation:

```
        if x < y goto L1
        goto LFalse
L1:     if a = b goto LTrue
        goto LFalse
        ...
```

These labels will be generated later on, and will be inserted to the corresponding places

LTrue:

LFalse:

Flow-of-Control Statements

UC Santa Barbara

If-then-else

- Branch based on the result of Boolean expression

Loops

- Evaluate condition before loop (if needed)
 - Evaluate condition after loop
 - Branch back to the top if condition holds
- Merges test with last block of loop body

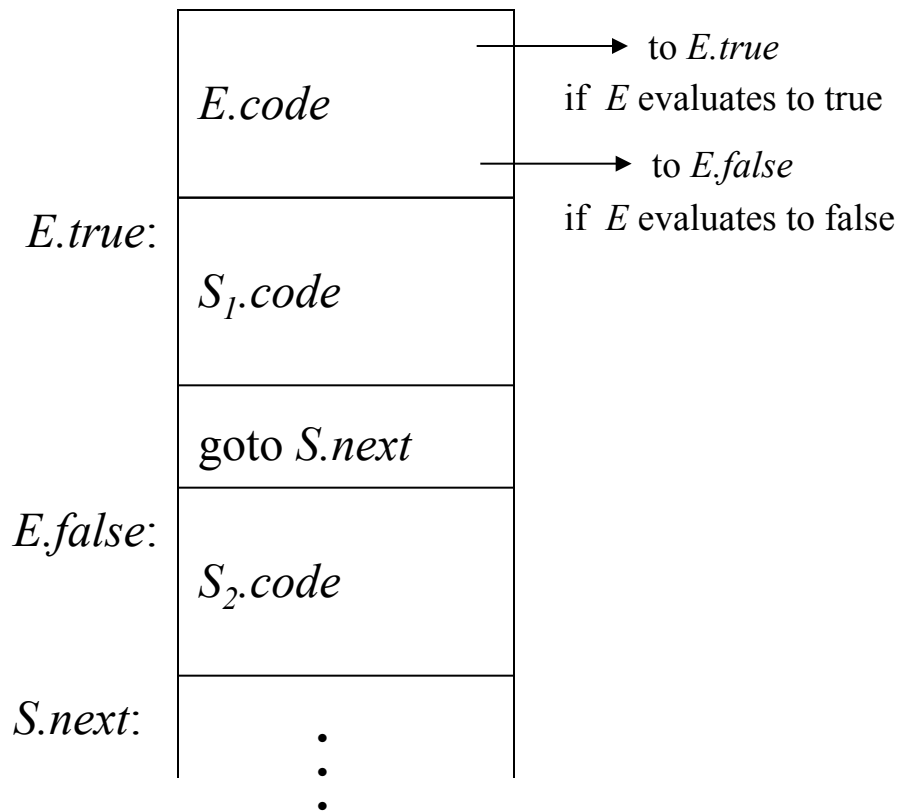

While, for, do, and until all fit this basic model

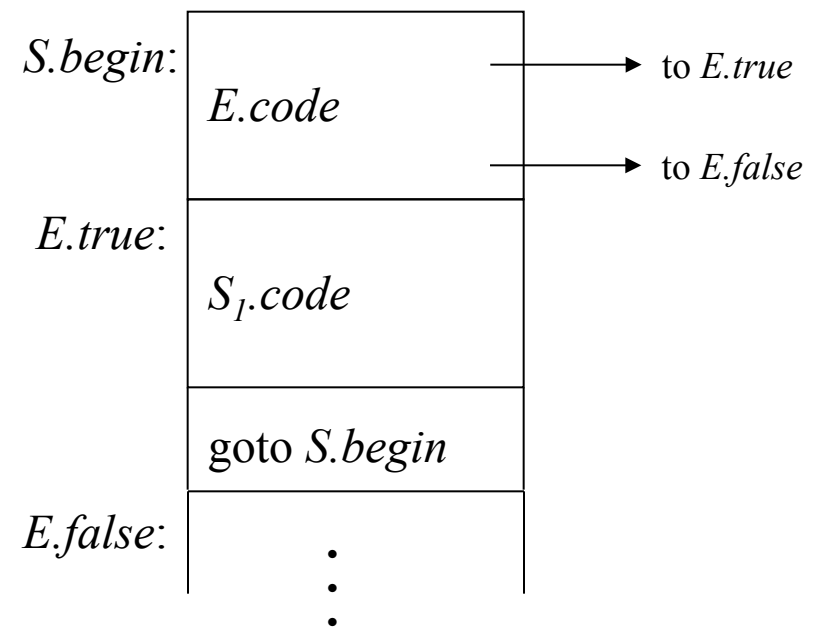

Flow-of-Control Statements: Code Structure

UC Santa Barbara

$S \rightarrow \text{if } E \text{ then } S_1 \text{ else } S_2$

$S \rightarrow \text{while } E \text{ do } S_1$

Another approach is to place *E.code* after *S₁.code*

Flow-of-Control Statements

UC Santa Barbara

Attributes : *S.code*: sequence of instructions that are generated for *S*
 S.next: label of the instruction that will be executed immediately after *S*
 (*S.next* is an inherited attribute)

Productions

$S \rightarrow \text{if } E \text{ then } S_1 \text{ else } S_2$

$S \rightarrow \text{while } E \text{ do } S_1$

$S \rightarrow S_1 ; S_2$

Semantic Rules

$E.true \leftarrow \text{newlabel}();$
 $E.false \leftarrow \text{newlabel}();$
 $S_1.next \leftarrow S.next;$
 $S_2.next \leftarrow S.next;$
 $S.code \leftarrow E.code \parallel \text{gen}(E.true \text{ ':'}) \parallel S_1.code$
 $\quad \parallel \text{gen}(\text{'goto' } S.next) \parallel \text{gen}(E.false \text{ ':'}) \parallel S_2.code ;$

$S.begin \leftarrow \text{newlabel}();$
 $E.true \leftarrow \text{newlabel}();$
 $E.false \leftarrow S.next;$
 $S_1.next \leftarrow S.begin;$
 $S.code \leftarrow \text{gen}(S.begin \text{ ':'}) \parallel E.code \parallel \text{gen}(E.true \text{ ':'}) \parallel S_1.code$
 $\quad \parallel \text{gen}(\text{'goto' } S.begin);$

$S_1.next \leftarrow \text{newlabel}();$
 $S_2.next \leftarrow S.next;$
 $S.code \leftarrow S_1.code \parallel \text{gen}(S_1.next \text{ ':'}) \parallel S_2.code$

Example

UC Santa Barbara

Input code fragment:

```
while (a < b) {  
    if (c < d)  
        x = y + z;  
    else  
        x = y - z  
}
```

```
L1:    if a < b goto L2  
        goto LNext  
L2:    if c < d goto L3  
        goto L4  
L3:    t1 := y + z  
        x := t1  
        goto L1  
L4:    t2 := y - z  
        x := t2  
        goto L1  
LNext:    ...
```

Memory Layout

UC Santa Barbara

Placing run time data structures

- **Stack and heap share free space**
- **Fixed-size areas together**
- **For compiler, this is the entire picture**

Alignment and padding

- Machines have alignment restrictions
 - 32-bit floating point numbers and integers should begin on a full-word boundary (32-bit boundary)
- Place values with identical restrictions next to each other
- Assign offsets from most restrictive to least
- If needed, insert padding (space left unused due to alignment restrictions) to match restrictions

Memory Allocation

UC Santa Barbara

$P \rightarrow D$

$D \rightarrow D; D$

$D \rightarrow id : T$

$T \rightarrow char \mid int \mid float \mid array[num] \text{ of } T \mid \text{pointer } T$

Attributes: $T.type, T.width$

Basic types: $char$ width 4, $integer$ width 4, $float$ width 8

Type constructors: $array(size,type)$ width is $size * (width \text{ of } type)$
 $pointer(type)$ width is 4

- Enter the variables to the symbol table with their type and memory location
- Set the type attribute $T.type$
- Layout the storage for variables
 - Calculate the offset for each local variable and enter it to the symbol table
 - Offset can be offset from a static data area or from the beginning of the local data area in the activation record

Translation Scheme for Memory Allocation

UC Santa Barbara

```
P → {offset ← 0;} D
D → D; D
D → id : T {enter(id.name, T.type, offset); offset ← offset + T.width; }
T → char { T.type ← char; T.width ← 4; }
   | int { T.type ← integer; T.width ← 14; }
   | float { T.type ← float; T.width ← 8; }
   | array[num] of T1 { T.type ← array(num.val, T1.type);
                       T.width ← num.val * T1.width; }
   | pointer T { T.type ← pointer(T1.type); T.width ← 8; }
```

- Note that if the size of the array is not a constant we cannot compute its width at compile time
- In that case, allocate the memory for the array in the heap and allocate the memory for the pointer to the heap at compile time

Array Accesses

UC Santa Barbara

First, must agree on a storage scheme:

Row-major order

(most languages)

Lay out as a sequence of consecutive rows

Rightmost subscript varies fastest

A[1,1], A[1,2], A[1,3], A[2,1], A[2,2], A[2,3]

Column-major order

(Fortran)

Lay out as a sequence of columns

Leftmost subscript varies fastest

A[1,1], A[2,1], A[1,2], A[2,2], A[1,3], A[2,3]

Indirection vectors

(Java)

Vector of pointers to pointers to ... to values

Takes more space

Locality may not be good

Laying Out Arrays

UC Santa Barbara

The Concept

A

1,1	1,2	1,3	1,4
2,1	2,2	2,3	2,4

Row-major order

A

1,1	1,2	1,3	1,4	2,1	2,2	2,3	2,4
-----	-----	-----	-----	-----	-----	-----	-----

Column-major order

Indirection vectors

These have distinct & different cache behavior

The order of traversal of an array can effect the performance

How do we insert the calculation for arrays

- If I access element $A[2,3]$, what address is storing my variable?

	0	1	2	3	4	5	6	7
A	1,1	1,2	1,3	1,4	2,1	2,2	2,3	2,4

Need to map $i = 2, j = 3$ to array element 6

- If $i = 2$, and we start at 1, we need to skip over one row (Row 1) worth of stuff. In general, we would skip over $(i - low)$ rows (low is the number you start counting at for your arrays - in the example, it is 1)
- Each row is some number of elements in length ($high - low + 1$)
 $= (4 - 1) + 1 = 4$
- Once you get to the correct row, we just add $j - low$ to get the right index
 $= (3 - 1) = 2$

Computing an Array Address

UC Santa Barbara

1-D array: $A[i]$

- $@A + (i - \text{low}) \times \text{sizeof}(A[1])$

Almost always a power of 2, known at compile-time \Rightarrow use a shift for speed

Base of A (starting address of the array)

$\text{int } A[1:10] \Rightarrow \text{low is } 1$
Make low 0 for faster access (save a subtraction)

Two-D array: $A[i_1, i_2]$

Expensive computation!
Lots of +, -, x operations

Row-major order, two dimensions

$$@A + ((i_1 - \text{low}_1) \times (\text{high}_2 - \text{low}_2 + 1) + i_2 - \text{low}_2) \times \text{sizeof}(A[1])$$

Column-major order, two dimensions

$$@A + ((i_2 - \text{low}_2) \times (\text{high}_1 - \text{low}_1 + 1) + i_1 - \text{low}_1) \times \text{sizeof}(A[1])$$

Indirection vectors, two dimensions

$$*(A[i_1])[i_2] \quad \text{— where } A[i_1] \text{ is, itself, a 1-d array reference}$$
