## Abstract

Buffer overflows are still a significant problem in programs written in C and C++. In this paper we present a bounds checker called PAriCheck that inserts dynamic runtime checks to ensure that attackers are not able to abuse a buffer overflow vulnerability. The main approach is based on checking pointer arithmetic rather than pointer dereferences when performing bounds checks. The checks are performed by assigning a unique label to each object and ensuring that the label is associated with each memory location that the object inhabits. Whenever pointer arithmetic occurs, the label of the base location is compared to the label of the resulting arithmetic. If the labels differ, an out of bounds calculation has occurred. Benchmarks show that PAriCheck has a low performance overhead compared to similar bounds checkers. This paper demonstrates that using bounds checkers for programs or parts of programs running on high-security production systems is a realistic possibility.

## Abstract

Buffer overflows are still a significant problem in programs written in C and C++. In this paper we present a bounds checker called PAriCheck that inserts dynamic runtime checks to ensure that attackers are not able to abuse a buffer overflow vulnerability. The main approach is based on checking pointer arithmetic rather than pointer dereferences when performing bounds checks. The checks are performed by assigning a unique label to each object and ensuring that the label is associated with each memory location that the object inhabits. Whenever pointer arithmetic occurs, the label of the base location is compared to the label of the resulting arithmetic. If the labels differ, an out of bounds calculation has occurred. Benchmarks show that PAriCheck has a low performance overhead compared to similar bounds checkers. This paper demonstrates that using bounds checkers for programs or parts of programs running on high-security production systems is a realistic possibility.

## 1 Introduction

Security has become an important concern for all computer users. Worms and hackers are a

part of every day Internet life. A particularly dangerous vulnerability is the buffer overflow. This type of vulnerability can be used to perform a number of attacks. A first type of attack is the code injection attack, where attackers are able to insert code into the program's address space and can subsequently execute it. However, such a vulnerability can also lead to non-control data attacks, where attackers overwrite data to change the behavior of the program. Programs written in C are particularly vulnerable to such attacks. Attackers can use a range of vulnerabilities to inject code. The most well known and most exploited buffer overflow is, of course, the standard buffer overflow: attackers write past the boundaries of a stack-based buffer, overwrite the return address of a function and make it point to their injected code (or they could execute existing code). When the function subsequently returns, the code injected by the attackers is executed [3]. While this type of vulnerability has existed for a long time, it is still an active research topic with both attackers [35] and defenders [2] continually improving their techniques, both in terms of effectivity, efficiency and automation.

Buffer overflows also still occur often in real world programs: according to the NIST's National Vulnerability Database [30], 465 buffer overflow vulnerabilities were reported in the

first 10 months of 2008, making up 10% of the 4,668 vulnerabilities reported in that period. Of those buffer overflows vulnerabilities, 347 had a high severity rating. As a result, buffer overflows make up 15% of the 2,324 vulnerabilities with a high severity rating reported in those 10 months.

Many countermeasures exist to protect against these types of problems [18, 41]. They range from safe languages [21, 31, 17, 26, 40] that remove the vulnerabilities entirely, to bounds checkers [22, 34, 16, 2] that will perform runtime checks for out-of-bounds accesses, to very lightweight countermeasures that prevent certain memory locations from being overwritten [15, 12, 43] or prevent attackers from finding or executing injected code [37, 6, 5]. Most bounds checkers have a significant amount of performance overhead related to the checks that they insert. Others require significant architectural changes that require a specific memory allocation scheme to be used. Yet others rely on static analysis techniques to speed up performance, sometimes at the expense of completeness.

In this paper we present PAriCheck (Pointer Arithmetic Checker), a new approach to protecting C applications against buffer overflows by performing efficient dynamic bounds checks. PAriCheck does not require large infrastructural changes like using a specific type of memory allocator and is compatible with existing libraries. To achieve compatibility with existing code, we do not change pointer representation and to achieve efficient lookups we also do not store bounds information for objects.<sup>1</sup> Instead we store a unique ID, called a label, for every object and ensure that the label is associated with the entire memory area that is associated with that object. We then instrument pointer arithmetic to compare the label of the memory location resulting from the arithmetic with the label of the base object. If the labels differ, an out-of-bounds calculation has occurred. According to the C standard [23], this would result in undefined behavior if the

---

<sup>1</sup>We will use the term object to refer to an array, a structure/union or an area of memory that has been dynamically allocated

out-of-bounds calculation was larger than 1 element out of bounds and as a result we could terminate the program. However, as noted in [34], a significant amount of programs that are not vulnerable to buffer overflows will perform out-of-bounds calculations that are larger than 1 element out-of-bounds. To provide support for these programs, we use a technique similar to the those described in [34, 16]. As a result, PAriCheck is also compatible with these programs.

The rest of this paper is structured as follows: Section 2 briefly recaps buffer overflows and how attackers can abuse these type of vulnerabilities. Section 3 discusses the design of our countermeasure, while Section 4 examines the details of our prototype implementation. Section 5 presents an evaluation of our prototype by benchmarking it both in terms of performance and memory overhead. This section also discusses the security impact of our countermeasure. In Section 6 we compare our bounds checker to other bounds checkers and to other countermeasures. Finally, Section 7 presents our conclusion.

## 2 Buffer overflows

Buffer overflows are the result of an out of bounds write operation on an array. In this section we briefly recap how an attacker could exploit such a buffer overflow. A detailed overview of how a buffer overflow can be exploited, can be found in [3].

Buffers can be allocated on the stack, the heap or in the data/bss section in C. For arrays that are declared in a function body, space is reserved on the stack. Buffers that are allocated dynamically (using the *malloc* function, or some other variant), are put on the heap, while arrays that are global or static are allocated in the data/bss section. The array is manipulated by means of a pointer to the first byte. Bytes within the buffer can be addressed by adding the desired index to this base pointer.

Listing 1: A C function that is vulnerable to a

buffer overflow.

```
void copy(char* src, char* dst) {
    int i = 0;
    char curr = src[0];
    while(curr) {
        dst[i] = curr;
        i++;
        curr = src[i];
    }
}
```

At run-time, no information about the array size is available. Consequently, most C-compilers will generate code that will allow a program to copy data beyond the end of an array. This behavior can be used to overwrite interesting data in the adjacent memory space.

On the stack this is usually the case: it stores the addresses to resume execution at, after a function call has completed its execution. This address is called *the return address*. Manipulating the return address might give the attacker the possibility to execute arbitrary code. In addition to the return address, the contents of other variables on the stack might also be overwritten. This could be used to manipulate the results of previous calculations or checks.

Likewise, the heap also often contains important memory management information right before the allocated buffer. By manipulating this information, an attacker can control the execution path of the processor when the application frees the allocated memory.

Listing 1 shows a straightforward string copy function. Improper use of this function can lead to a buffer overflow, because there is no validation that the destination buffer can actually hold the input string. This function will be used throughout the paper as a running example to explain the workings of the proposed algorithm.

Many current countermeasures try to protect applications by protecting the return addresses and other important management information. However, this isn't enough to thwart buffer overflow attacks. The following subsections show how someone might be able to successfully attack an application, without overwriting the return address. These attacks

will also be protected against by PARICheck.

## 2.1 Non-control Data Attacks

An example of how an attacker can modify the execution flow, without overwriting important management information, comes from a real bug present in old versions of the UNIX login program. Listing 2 shows a simplified version of the algorithm used to authenticate a user.

Listing 2: A simplified version of the UNIX login function.

```
int login() {
    char username[8];
    char hash_pw[8];
    char pw[8];
    printf("login:");
    gets(username);
    // Put stored hash
    // in hashed_pw
    lookup(username, hash_pw);
    printf("password:");
    gets(pw);
    if (eq(hash_pw, hash(pw)))
        return OK;
    else
        return INVALID_LOGIN;
}
```

Since it is impossible to specify the maximum number of characters that should be read from the input, using the *gets* function, the attacker might trigger a buffer overflow. By entering a password that is longer than eight characters, the array that stores the hash of the password can be overwritten. Hence, if the attacker enters an eight-character password, and appends this password with its eight-character hash value, the original hash value will be overwritten with the value supplied by the attacker. This will cause the login application to authenticate the attacker.

Attacks like this do not inject code, but they can be used to modify the behavior of an application to the benefit of an attacker. Even though the example presented here occurred decades ago, the problem is still relevant today (see [11]). Furthermore, state of the art countermeasures often do not detect this type of buffer overflows.

## 2.2 Attacker-controlled Offsets

Changing the execution flow of an application can sometimes be accomplished without executing an overflow of contiguous memory. Listing 3 shows an example of a function that contains such a flaw. In this example, the attacker controls the data of the three parameters. However, unlike in previous examples, no contiguous buffer overflow is used to take over the application.

Listing 3: A function that is vulnerable to an arbitrary code injection attack

```
void (*log_msg)(char *msg)
    = printf;

void change_and_log(int *buffer ,
    int offset , int value) {
    buffer[offset] = value;
    log_msg(" Buffer _has _changed");
}
```

The function in listing 3 modifies the contents of a buffer, and sends a message to the log. Logging is done by calling a function pointer to a function that logs the message. In this example, the log is written to the console (using the *printf* function).

By adjusting the values of the *offset* parameter, the attacker is able to overwrite the *log\_message* function pointer. If the location of *buffer* is known, and the location of the *log\_message* pointer is also known, the offset can be calculated as the difference between *buffer* and *log\_message*. Then, the attacker-controlled *value* is written to this location. After this assignment, the *log\_message* function pointer is called, which transfers control to whatever address the attacker wrote in it in the previous step. This could for instance be an address in *buffer* that contains malicious machine code.

## 2.3 Integer Errors

Integer errors [9] are not exploitable vulnerabilities by themselves, but exploitation of these errors could lead to a situation where the program becomes vulnerable to a buffer overflow.

Two kinds of integer errors that can lead to exploitable vulnerabilities exist: integer overflows and integer signedness errors. An integer overflow occurs when an integer grows larger than the value that it can hold. The ISO C99 standard [23] mandates that unsigned integers that overflow must have a modulo of  $\text{MAXINT}+1$  performed on them and the new value must be stored. This can cause a program that does not expect this to fail or become vulnerable: if used in conjunction with memory allocation, too little memory might be allocated causing a possible heap-based buffer overflow.

Integer signedness errors occur as follows: when the programmer defines an integer, it is assumed to be a signed integer, unless explicitly declared unsigned. When the programmer later passes this integer as an argument to a function expecting an unsigned value, an implicit cast will occur. This can lead to a situation where a negative argument passes a maximum size test but is used as a large unsigned value afterwards, possibly causing a stack-based or heap-based overflow if used in conjunction with a copy operation (e.g. *memcpy* expects an unsigned integer as size argument and when passed a negative signed integer, it will assume this is a large unsigned value).

## 3 Countermeasure Design

In this section we describe our general approach taken by PAriCheck.

### 3.1 Approach

The vulnerabilities described in Section 2 are the result of out of bounds operations on arrays or via pointers. One approach to protecting against this type of attack is to perform bounds checking: ensuring that no access is allowed out of bounds of the memory area that an object inhabits. However, bounds checking in C is a hard problem, due to the pointer manipulation that is freely allowed in C and the lack of bounds information that is available at runtime. Most bounds checkers will protect against attacks on those vulnerabilities

by ensuring that a pointer does not go out of bounds by storing extra information with the pointer. The bounds checker will then check if the pointer is pointing to the object that it is supposed to be pointing to when it is dereferenced. PAriCheck is based on the observation in [22] that pointers go out of bounds as the result of an arithmetic operation. As a result, the main principle behind our countermeasure is that we only perform out of bounds checks on the results of pointer arithmetic. If we ensure that pointers that go out of bounds via arithmetic are made invalid, then an out of bounds access via these pointers is not possible.

Our countermeasure will not change the way that pointers are represented, so that we stay compatible with existing non-protected code. Unlike other countermeasures, we also do not store bounds information for objects or pointers. This is the main efficiency improvement made by our countermeasure: by not storing bounds information for objects, we do not need complex checks to find out which object a pointer is pointing into, which results in more lightweight lookups and checks.

Instead, we store a unique number for the memory area (called a label) that an object inhabits. When we perform pointer arithmetic, we look up the label of the memory location that we start the operation with and then look up the label of the resulting pointer that results from the arithmetic operation. If the labels match, the pointer is still pointing within the bounds of the object; if they differ, then we have an out of bounds calculation. If we were to use size information the lookup would be more complex, instead of comparing two labels we would have to look up the size information of the memory area that the current pointer is pointing into and then make sure that the arithmetic being performed does not go beyond these bounds. While the last check is fairly cheap, finding the memory area that the object is pointing to is more expensive.

These labels will take up a particular amount of memory. To be able to use a single label for more than one byte of memory, we make sure that all objects are a multiple of  $2^k$  bytes and we also ensure that the object's base address is

aligned to  $2^k$ . We call such a memory area of  $2^k$  bytes a region. An object can inhabit multiple regions and we will need the same label for each region. The region's size is fixed per application and the optimal size will depend on the application's memory use. We discuss this further in Section 4. When an object is allocated (either by entering a function, when the program starts for global/static memory or by explicit dynamic allocation), we assign a label to the regions that the object inhabits. When the object is later deallocated, we do not remove the label as a new label will be assigned when the object's previous regions are reused. If an object inhabits multiple regions, then it will be assigned the same label multiple times. Since all regions that an object inhabits contain the same label, any copy to any location within the object will be considered in-bounds. Since the label is associated with the memory region, a pointer can point to any location within the object: the bounds check will be performed correctly by looking up the label associated with the memory location that the pointer is pointing to.

Listing 4: A C function that calls the copy function from Listing 1

```
int main() {
char src1[8], dst1[100];
char src2[100], dst2[8];
// init all strings with a
// null-terminated string
// of their maximum size
copy(src1, dst1);
copy(src2, dst2);
}
```

Listing 4 contains a small program that calls the vulnerable copy function described in 1. Figure 1 has a graphical representation of what the program looks like when  $k$  is set to 5 (i.e., each region is 32 bytes large). The full lines represent the memory area that was originally requested for the object, while the dotted lines represent the regions that the object's inhabits.

Listing 5: Transformed copy and main functions from Listings 1 and 4

```
int main() {
```

Figure 1: Memory layout of main in PAriCheck

```

char src1[32], dst1[128];
char src2[128], dst2[32];
labelsspace(&src1, sizeof(src1), 1);
labelsspace(&dst1, sizeof(dst1), 2);
labelsspace(&src2, sizeof(src2), 3);
labelsspace(&dst2, sizeof(dst2), 4);
// init all strings with a
// null-terminated string
// of their maximum size
copy(src1, dst1);
copy(src2, dst2);
}
curr = *src i;
}

```

```

void copy(char *src, char *dst)
{
int i = 0; char curr;
char *dsti, *srci;
int label1, label2;
curr = *src;
while (curr) {
label1 = getlabel(dst);
label2 = getlabel(dst+i);
if (label1 == label2) {
dsti = dst+i;
*dsti = curr
}
label1 = getlabel(src);
label2 = getlabel(src+i);
if (label1 == label2) {
srci = src+i;
}
}

```

Listing 5 contains an example of how our basic pointer arithmetic checks are performed (Section 4 contains a complete transformation of the copy function) on the program 4. In the loop in copy, we lookup the label of the memory that *dst* is pointing to and then compare it to the label of the memory location that *dst+i* would point to. Similar checks are done for *src*.

When main calls *copy(src1, dst1)*, the loop will stop at *src+7*. Because *src* is null-terminated all label checks will be correct. In the case of *copy(src2, dst2)*, the label of *dst2+32* will be different from the label of *dst2*. This means we have tried to access an out-of-bounds memory location. The next section describes how we handle these situations.

### 3.2 Handling out-of-bounds pointers

When we detect an out of bounds access we use a technique similar to the ones used in [34, 16]. We make the pointer point to an invalid memory location: on 32-bit versions of Linux, all memory above 3GB is considered kernel space. Accessing this memory from a regular program will cause the program to crash. So we set the

pointer to point to a unique value above 3GB which we will call an OOB-pointer. We then allocate a block of memory where we store the label of the base pointer, the resulting memory location that would have been the result of our arithmetic (which we call the intended pointer) and the OOB-pointer value. We store this information in a linked list. When we perform an arithmetic operation using an OOB-pointer, we look up the correct object in the linked list and then use the intended pointer as the value to perform the arithmetic operation on. Then we perform a bounds check again by comparing the stored label with the label of the result of the arithmetic operation. If the object goes inbounds again, then we set the pointer to the result of the operation, otherwise we create a new OOB-object which contains the updated information and set the pointer to the new OOB-pointer.

As a result, if the pointer is never accessed while out-of-bounds, the program continues to function correctly.

### 3.3 Uninitialized pointers

Uninitialized pointers are not protected by our approach: if the program performs arithmetic on an invalid pointer, then an invalid label (which will most likely be 0) will be read from the table and compared to the label of the result of the arithmetic (also most likely 0). Our approach does not cover this possible vulnerability because we assume that this behavior is rare. However if protection against this type of error is desired, it can easily be added by initializing all pointers that are not initialized by default to a specific value (e.g. 3GB) and assigning a label to this location. This will ensure that any arithmetic done on uninitialized pointers will be detected by our countermeasure.

### 3.4 Casting a pointer to an integer and back again

PAriCheck will protect against out of bounds violations caused by invalid pointer arithmetic and invalid array index accesses. These are the most common types of bounds violations

that occur in a program. However PAriCheck will not protect programs that cast a pointer to an integer, then perform the calculation and later cast the resulting value back to a pointer. This is a limitation in our approach that stems from the fact that the arithmetic is no longer performed on a real pointer and as such will not be detected by our approach. While this is a limitation in our approach, the vast majority of buffer overflows occur as the result of invalid pointer arithmetic (e.g. an out-of-bounds *strcpy*) or invalid array index accesses. Other bounds checkers generally do not protect against this either: the casting back of the pointer will initialize that pointer to point to a valid memory location (which may be out of bounds as compared to the original pointer) [?, Ruwase:2004:PDB]

### 3.5 Overflows in structures

A limitation in our approach, one that is also present in most other bounds checkers, is the fact that we do not protect pointers in a structure from other information in that structure. This limitation is a result of the C standard which specifically allows code to access the entire memory of a structure from a pointer to an element in the structure (e.g. to allow for instructions like `memset(&strct,0,sizeof(strct));`). This makes it impossible to check for these kinds of buffer overflows while remaining compatible with the C standard.

### 3.6 Bounds checking arrays

In C there is a difference between array types and pointer types. If an array is declared as `array[size]`, then the use of `array[index]` means we are accessing an array via its index. While the array type can be used interchangeably with a pointer type in C, the two are handled differently by the compiler. Array types have a size associated with them during compilation, which means we can look up the array's size when accessing an array type via an index. As a result, bounds checking array types is a trivial operation: we can simply insert a check to make sure that the index used to access an ele-

ment in the array is smaller than the size of the array. This type of check is trivial and does not occur a significant amount of overhead and this is also the approach used for checking arrays in our countermeasure.

Variable length arrays are translated into calls to *alloca* by the framework we use to implement our transformation, which means that pointer arithmetic will be performed and thus will be checked. However if they were handled as real variable length arrays, our checker would just add the variable denoting the size in the check instead of the compile-time size.

### 3.7 Unprotected code

Code that is linked to code that is protected by PARICheck will work without issues. Any objects allocated in this code will of course not have been labeled and will thus not enjoy protection. Given that these objects have not been labeled, that also means they do not have to be aligned. When a label lookup is performed for these objects the label will simply be 0 as will the result of the arithmetic, unless the result of the arithmetic points into a protected object. If an unprotected object overflows into a protected object then the resulting out of bounds access will also be detected because the label of the unprotected object (0) will differ from the label of the protected object.

## 4 Prototype Implementation

Our implementation has many facets. The most important code transformations that result in the actual checks being inserted whenever pointer arithmetic is performed was done using CIL [32]. However to ensure that all stack-based objects are our minimum size and allocated on our alignment boundary, some changes to GCC were done. Finally we modified the malloc, realloc and calloc functions to ensure that objects are aligned correctly, are a multiple of our minimum size, and are assigned a label.

We place the labels in a sequential area of memory that is big enough to hold labels for

all the regions.<sup>2</sup> In our prototype implementation labels are 4 bytes large. Because a label for every byte would waste too much memory, we have a default region size of 32 bytes. However, the region size can be chosen depending on the application. Our default region size ensures that we only need 1 label per 32 bytes. This means that the labels will take up only 12% of memory, while a label for every byte would have unacceptable overhead. It also means that every object will take up 32 bytes. For example programs with 16 byte regions will have a 24% label overhead, but if most objects are close to 16 bytes in size and we would have an internal fragmentation of 100% if we used a region size of 32 bytes. So for a program with many smaller or larger chunks it becomes more interesting to set the region size closer to the size of the most used objects.

In our benchmarks we use two different region size depending on the objects used in the programs: most programs have a region of 32 bytes while others have a region of 16 bytes.

To find the correct entry of a memory location in the label area, we shift the address right by  $\log_2(\text{region size})$  bits (i.e., by 5 bits for our default region size of 32 bytes), and then use the resulting value as an offset into the table. This allows for fast lookups of labels.

Figure 6 is a sample transformation<sup>3</sup> of the code in Figure 1. This transformation demonstrates how our bounds checker performs its checks:

Listing 6: Transformed sample program

```
void copy(char *src, char *dst)
{
    int i = 0; char curr;
    char *mem5; char *mem6;
    char *mem7;
    char *dsti; char *srci;
    int label1; int label2;
    char *oobdst; char *oobsrc;
```

<sup>2</sup>This area of memory is virtual memory, which means that only pages where we actually store a label will use physical memory.

<sup>3</sup>Some minor editorial changes were made: variable names have been changed to make the code more readable, some excessive curly brackets were removed, etc.

```

mem5 = src + 0;
curr = *mem5;
while (curr) {
  if (dst < 3221225472) {
    dsti = dst + i;
    label1 = getlabel(dst);
  } else {
    oobdst = getoob(dst);
    label1 = getooblable(dst);
    dsti = oobdst + i;
  }
  label2 = getlabel(dsti);
  if (label1 != label2)
    dsti = setoob(label1, dsti);
  mem6 = dsti;
  *mem6 = curr;
  i ++;
  if (src < 3221225472) {
    src0 = src + i;
    label1 = getlabel(src);
  } else {
    oobsrc = getoob(src);
    label1 = getooblable(src);
    src0 = oobsrc + i;
  }
  label2 = getlabel(src0);
  if (label1 != label2)
    src0 = setoob(label1, src0);
  mem7 = src0;
  curr = *mem7;
}
}

```

The pointer arithmetic has been transformed as follows: our countermeasure checks if *dst*'s address is below 3GB. If it is, the label for *dst* is looked up and the arithmetic  $dst + i$  is performed. Then the label for the buffer is looked up. If *dst* is above 3GB, then it went out of bounds earlier and we must look up the out-of-bounds value and look up the original label. We then perform the arithmetic  $out\_of\_bounds\_dst + i$ . The resulting arithmetic and labels of either part of the if statement will be stored in *dsti* and *label1*, respectively. We then look up the label of this newly calculated address and compare it to the label in *label1*. If the labels match, the arithmetic was in bounds, if it was not, the arithmetic went out of bounds and we assign an out-of-bounds value to *dsti*,

which will contain a unique ID (3GB + unique number), the labeling information and the original arithmetic. Afterwards, *dsti* is used as the result of our arithmetic in the operation we must perform. If the arithmetic would go out-of-bounds in this case then the *\*mem\_6 = curr* statement will try to dereference an invalid memory location, causing the program to crash. Similar checks are performed for *src*.

## 5 Evaluation

These extra checks come at a cost: both in terms of performance and in terms of memory overhead. To evaluate how high the performance overhead of our bounds checker is, we ran the Olden benchmarks. All benchmarks were performed on a single machine: an Intel Core 2 Duo 3.16 Ghz with 8GB of RAM running Ubuntu 08.04 with kernel 2.6.24.3. All benchmarks were compiled with using gcc-4.3.0-20070803 with the -O2 parameter and were linked to dlmalloc 2.7.2 (the original one for the baseline benchmark and our modified version for our bounds checker).

Two sets of benchmarks were performed: the SPEC CPU2000 integer benchmarks and the Olden benchmarks. The SPEC CPU2000 integer benchmarks provide us with a measurement of very CPU intensive programs, while the Olden benchmarks allow us to measure applications that are very memory intensive. The SPEC CPU2000 benchmarks were run, as is, with the default parameters which allowed for a reportable run. For the Olden benchmarks, a number of options were chosen that would let the program run for a significant amount of time and would let it use a significant amount of memory. The first column of Table 1 contains the program names and, for the Olden benchmarks, the parameters that we used to achieve these results. For editing purposes we abbreviated the amounts: in the table a K is used to denote 1000 and M is used to denote 1000000. As mentioned in Section 4, we use a default object alignment and object size of 32 bytes.

To perform our transformations we use the `dosimpleMem` option of the CIL infrastructure.

This option will simplify all memory operations and makes our transformation easier. We then apply our bounds checker. However using this option has an impact on performance. Since we want to measure the overhead of only our transformations rather than other transformations we supply benchmarks for programs compiled regularly with GCC, compiled with CIL with `dosimpleMem` and finally compiled with CIL with our bounds checker.

In Section 5.1 we discuss our performance overhead, while section 5.2 discusses the memory overhead associated with PARICheck.

### 5.1 Performance overhead

Columns 2 to 4 in Table 1 contain the runtime in seconds of our benchmarks. Column 2 is simply the original program compiled with the default `gcc-4.3.0-20070803`. While the third column is the benchmark run with Cil with the option `dosimplemem`. As can be seen, in most cases the performance difference between Cil and Gcc is negligible. Since we aim at measuring the overhead of our transformation rather than the impact of various Cil transformations, column 5 contains the relative overhead of Column 4 over Column 3, i.e. the fifth column in Table 1 is the relative performance overhead of the runtime of PARICheck compared to the original program compiled with Cil.

The average overhead of our countermeasure is 49.4% for the SPEC CPU2000 integer benchmarks and 5.5% for the Olden benchmarks and a total average overhead over all benchmarks of 42.7%. These overheads show that by applying dynamic checks on all pointers can be done efficiently. However, some overheads, like the overhead of `vpr`, are relatively high (although better than existing countermeasure that do not rely on static analysis for optimizations). For a production-level implementation of our approach, these overheads can be further improved by performing compile-time optimizations on our checks: removing redundant checks (e.g. if an arithmetic operation like `src[i]` has been checked and we can be sure that if neither `i` nor `src` change then the following check can be removed), moving checks

outside of loops, etc. [10].

### 5.2 Memory overhead

Table 1 also contains the memory usage in megabytes of the programs compiled with Cil and compiled with our bounds checker in columns 5 and 6 respectively. Because the overhead of compiling with Gcc and with Cil is the same, we have omitted the Gcc column. The last column shows the memory overhead of using our countermeasure. These were measured by adding a call to `getchar()` at the end of the program and then examining the `VmHWM` entry in `/proc/ <pid > /status`. This entry contains the peak resident set size which is the maximum amount of RAM the program has used during its lifetime. Since our tests were run with swap turned off this is equal to the actual maximum memory usage used by our program.

These results give us an average overhead of 10.5%. While not an insignificant overhead, we believe it is acceptable for high-security production systems. We can not compare our overhead with that reported by other bounds checkers as most other bounds checkers do not provide memory overhead measurements.

## 6 Related work

Many countermeasures have been designed to protect against code injection attacks. In Section 6.1 we compare our approach to other bounds checkers in detail. Then, in Section 6.2, we briefly highlight the differences between our approach and other approaches that protect programs against attacks on memory error vulnerabilities.

### 6.1 Bounds checkers

RTCC [36] is a modification of the Portable C Compiler that adds run-time array subscript and pointer bounds checking. To implement this, pointers are represented by three times their normal value, containing the current value of the pointer and the memory addresses of its lower and upper bounds. However, by changing the pointer representation

code can no longer be linked to existing code and the compiler can no longer implicitly cast an integer to a pointer.

Safe C [4] is a bounds checking countermeasure for C. It defines a kind of safe pointer that contains the following attributes: value, pointer base, size, storage class (heap, local, global) and capability (forever, never). The value attribute is the actual pointer, the base and size attributes are used for spatial check while the storage class and capability attributes are used for temporal checks. As with RTCC the pointer representation is changed, resulting in an incompatibility with existing code.

Jones and Kelly [22] developed a bounds checking technique that was used as the basis for the rest of the work described in this section. This bounds checker does not change the way pointers are represented in a program. This allowed bounds checked programs to be linked with existing compiled code. This suffers from very high performance overhead (up to 11x slower than the original program).

CRED [34] improves on the work described in [22] by providing support for arrays going out of bounds. Our handling of out-of-bounds pointers is based on the work developed in this paper. They also further improve on the technique by providing a few optimizations, one specific optimization which increases speed is that only character pointers and character arrays are checked. Checking this reduced set of pointers improves performance, however this approach still suffers from a high overhead (up to 11x when protecting all arrays) or does not protect programs against overflows involving non-character arrays or pointers (up to 2x when only protecting strings). Our approach protects all array types and all dynamically allocated memory at an overhead that is comparable and usually faster than the overheads reported by CRED when only protecting strings.

Dhurjati and Adve [16] discuss an efficient bounds checker that has a significantly lower overhead than previous bounds checkers. However their technique rests on the use of automatic pool allocation for a memory allocation, while our approach does not require such a sig-

nificant change of allocator. To be able to use the pool allocation, global static pointer analysis is required, which introduces scalability and modularity issues. This change of allocator also contributes to the difference in performance overhead for the Olden benchmarks between checked and unchecked programs [29], as is evidenced from the fact that some programs run faster with the bounds checker. They further improve on efficiency by applying compile-time optimizations to improve their performance. These techniques could also be applied to our bounds checker. We decided to focus on demonstrating that a purely dynamic approach can be made more efficient without changing the underlying architecture significantly or even applying compile-time optimizations.

WIT [2] discusses a very efficient technique to check whether instructions write to valid memory location. Their technique is based on static analysis that does a points-to analysis of the application. This analysis is then used to assign colors to memory locations and instructions. Each instruction has the same color as the objects it writes to. Then runtime checks are added to ensure that these colors are the same. This prevents instructions from writing to memory that they can not normally write to. The analysis is also used for optimization purposes: safe writes to memory do not get instrumented. This technique depends on a static points-to analysis, which can result in false negatives where an instruction is determined to be safe when it is not or it can assign an instruction or object a color that allows an unsafe instruction access to the object. WIT will also only prevent out-of-bounds writes, not out-of-bounds reads, while PAriCheck prevents both.

## 6.2 Alternative approaches

Many alternative approaches exist that try and protect against buffer overflow attacks. In this section we will briefly discuss the most important types of countermeasures. A more extensive discussion can be found in [41, 18].

### 6.2.1 Safe languages

Safe languages are languages where it is generally not possible for any known code injection vulnerability to exist as the language constructs prevent them from occurring. A number of safe languages are available that will prevent these kinds of implementation vulnerabilities entirely. There are safe languages [21, 20, 31, 28, 17, 26] that remain as close to C or C++ as possible, these are generally referred to as safe dialects of C. While some safe languages [13, 40] try to stay more compatible with existing C programs, use of these languages may not always be practical for existing applications.

### 6.2.2 Probabilistic countermeasures

Many countermeasures make use of randomness when protecting against attacks. Many different approaches exist when using randomness for protection. Canary-based countermeasures [15, 19, 27, 33] use a secret random number that is stored before an important memory location: if the random number has changed after some operations have been performed, then an attack has been detected. Memory-obfuscation countermeasures [14, 7] encrypt (usually with XOR) important memory locations or other information using random numbers. Memory layout randomizers [37, 6, 39, 8] randomize the layout of memory: by loading the stack and heap at random addresses and by placing random gaps between objects. Instruction set randomizers [5, 24] encrypt the instructions while in memory and will decrypt them before execution.

While these approaches are often efficient, they rely on keeping memory locations secret. However, programs that contain buffer overflows could also contain "buffer overreads" (e.g. a string which is copied via *strcpy* but not explicitly null-terminated could leak information) or other vulnerabilities like format string vulnerabilities, which allow attackers to print out memory locations. Such memory leaking vulnerabilities could allow attackers to bypass this type of countermeasure.

### 6.2.3 Separation and replication of information

Countermeasures that rely on separation or replication of information will try to replicate valuable control-flow information [38, 12] or will separate this information from regular data [42, 43]. This makes it harder for an attacker to overwrite this information using an overflow. Some countermeasures will simply copy the return address from the stack to a separate stack and will compare it to or replace the return addresses on the regular stack before returning from a function. These countermeasures are easily bypassed using indirect pointer overwriting where an attacker overwrites a different memory location instead of the return address by using a pointer on the stack. More advanced techniques try to separate all control-flow data (like return addresses and pointers) from regular data, making it harder for an attacker to use an overflow to overwrite this type of data.

While these techniques can efficiently protect against buffer overflows that try to overwrite control-flow information, they do not protect against attacks where an attacker controls an integer that is used as an offset from a pointer, nor do they protect against non-control-data attacks.

### 6.2.4 Execution monitors

In this section we describe two countermeasures that monitor the execution of a program and prevent transferring control-flow which could be unsafe.

Program shepherding [25] is a technique that monitors the execution of a program and will disallow control-flow transfers<sup>4</sup> that are not considered safe. An example of a use for shepherding is to enforce return instructions to only return to the instruction after the call site. The proposed implementation of this countermeasure is done using a runtime binary interpreter. As a result, the performance impact of this countermeasure is significant for some programs, but acceptable for others.

---

<sup>4</sup>Such a control flow transfer occurs when e.g., a *call* or *ret* instruction is executed.

Control-flow integrity [1] determines a program’s control flow graph beforehand and ensures that the program adheres to it. It does this by assigning a unique ID to each possible control flow destination of a control flow transfer. Before transferring control flow to such a destination, the ID of the destination is compared to the expected ID, and if they are equal, the program proceeds as normal. This approach, while strong and in the same efficiency range as our approach, does not protect against non-control data attacks.

## 7 Conclusion

The countermeasure described in this paper is an efficient dynamic bounds checker that can be used in high-security production systems with little effort and without requiring major architectural changes. PAriCheck protects against buffer overflow attacks that aim to overwrite control data or non-control data, by ensuring that the results of pointer arithmetic always points within the bounds of the base object. This is done by assigning a unique label for each object and associating this label with the entire memory area that the object inhabits. We then compare the label of the base address of the arithmetic operation with the label of the resulting arithmetic. If they differ, an overflow has occurred. In our benchmarks, PAriCheck has an average runtime overhead of 42.7%, which is a low overhead for this type of countermeasure. If we further combine our approach with static analysis techniques, including loop optimization and preventing redundant checks, performance overhead can be reduced even more.
